Abstract — The effect of a TiO$_2$ nanoparticle suspension (4 mg in 5 ml distilled water) doped or not with gold or iron, complexed or not with α- or β-cyclodextrin, on the mitotic division was studied. The treatment was performed in the M cellular mitotic cycle phase, in the meristematic tissue of Nigella damascena radicles, being analyzed the cytogenetic modifications. The cyclodextrin type and the ratio between cyclodextrin and titanium dioxide affect the percentage of normal cells and the chromosome aberration type. The TiO$_2$ complexed with α-cyclodextrin did not facilitate the reunion of the chromosome broken ends (absence of bridges in anaphase and in telophase). The titanium dioxide doped with iron, complexed with α- or β-cyclodextrin, also reduced the percentage of reunion of the broken ends of the chromosomes. These findings suggest the possibility of using doped or undoped TiO$_2$, complexed with α-cyclodextrin, in the anticarcinogen therapy.

Keywords - TiO$_2$-Au, TiO$_2$-Fe, cyclodextrin, chromosome mutations.

I. INTRODUCTION

Although the bimetallic particles were obtained long ago, their characterization was effected at the end of the 20th century [1]. The conjugation of bimetallic nanoparticles of AuNP type with oligonucleotides facilitates their use in molecular biology experiments and nanobiotechnology [2]. Other types of AuNP biconjugate with peptides, lipids, enzymes, drugs or viruses, were also obtained with application in nanobiotechnology, nanomedicine and/or in gene therapy.

Cyclodextrins are cyclic oligosaccharides. Depending on the glucose moiety number, they are classified in: α-cyclodextrins (with 6 glucose units), β-cyclodextrins (with 7 glucose units), and other greater homologues. The complexes with pharmaceutical products are usually better accepted and tolerated by the organism; they protect the bioactive substances against degradation (oxygen, humidity) and reveal controlled release properties. They are non-toxic and stable at the human digestive enzyme action. They are used in the obtaining of some pharmaceutical products, food additives, in agriculture, a/o [3]. In recent papers, the effect of β-cyclodextrin conjugate with TiO$_2$ [4] or with different bioactive substances [5], [6] was analyzed, in different experimental conditions.

In the present study nanoparticles of TiO$_2$-Au and TiO$_2$-Fe, dispersed in α- or β-cyclodextrin, the ratio between TiO$_2$ and cyclodextrin being 1:1 or 1:2, were used. The experiments were performed at a radiobiological tester plant (Nigella damascena L.), the chromosome aberrations from the meristematic radicle tissue being used as radiobiological indices.

II. MATERIAL AND METHODS

A. Nanoparticle achievement

1) Achievement of undoped and doped TiO$_2$ nanocrystals.

Undoped and doped titanium dioxide nanocrystals were synthesized by the sol-gel route, using the precursors: titanium isopropoxide, isopropyl alcohol, distilled water, nitric acid, gold (III) chloride trihydrate and ferrous nitrate. 5 ml of titanium isopropoxide (in drops) were mixed with 30
ml of isopropyl alcohol, under continuous stirring. After a few minutes of stirring, distilled water was added, continuously controlling the solution pH with nitric acid in order to avoid the precipitation. In the case of iron-doped and gold-doped TiO\textsubscript{2} ions, after the adjustment of the pH (2.5 for Au, 4.0 for Fe), the previously prepared solutions, namely iron nitrate and gold (III) chloride trihydrate were added under continuous stirring. In both cases, the gel was dried and washed in order to remove the secondary reaction products. The calcination was achieved in the oven, at a temperature of 250ºC for undoped TiO\textsubscript{2} and 500ºC for Au or Fe doped TiO\textsubscript{2}. The achieved nanocrystals based on titanium dioxide were used for complexation with cyclodextrins.

2) Achievement of complexes based on TiO\textsubscript{2} with \(\alpha\)-cyclodextrin or \(\beta\)-cyclodextrin.

\(\alpha\)- and \(\beta\)-cyclodextrins used for the co-crystallization with the previously attained titanium dioxide were of analytical purity (Fluka Chemie AG). In order to perform the complexation/co-crystallization, different solvents were used as suspension medium. In 1 ml distilled water, 0.054 g of \(\alpha\)-(\(\alpha\)-CD) or 0.067 g of \(\beta\)-cyclodextrin (\(\beta\)-CD) was dissolved, at a temperature of 50ºC. 0.075 g of undoped and doped TiO\textsubscript{2} was added to the solution, under continuous and vigorous stirring for 30 minutes at 50ºC. For the completion of the complexes crystallization, the solution was cooled and kept for 12 hours at a temperature of 5ºC, followed by filtration and drying of the achieved nanocrystals. The obtained materials were characterized by X-ray diffraction (XRD), scanning/transmission electron microscopy (SEM/TEM) and energy dispersive X-ray analysis (EDX).

Biological experiment

The experiment was performed in vivo, on the radiogenetic tester species Nigella damascena (Fam. Ranunculaceae). This species, used for a long time, is for its features: small somatic chromosome number different morphologically (2n=12), synchronized cell mitotic cycle, centromeres situated near the nuclear envelope, and absence of the bioactive substances in seeds [7], [8], [9]. The seeds with radicels of about 10 mm length were treated in the mitotic phase of the cellular cycle (for 2 hours), with a suspension of TiO\textsubscript{2}–Au or TiO\textsubscript{2}–Fe, complexed or not with \(\alpha\)-cyclodextrin, or with \(\beta\)-cyclodextrin (4 mg TiO\textsubscript{2}–Me in 5 ml distilled water). After treatment, the radicels were harvested for the cytogenetic investigations.

B. Cytogenetic investigations

The chromosome aberrations were analyzed in the radicular meristematic tissue, on squash preparation type, stain with a Carr solution. The normal and aberrant phases of the mitotic phase were analyzed, as well as the metabolic and structural modifications of the chromosomes and of the mitotic spindle. Although in the literature there are numerous papers about the environmental factors’ effect at the chromosome level, regarding the nanoparticles’ effect at the chromosome level the information is poor. The investigation performed at the Chinese hamster ovary, with TiO\textsubscript{2} particles, in the presence or absence of the UV light, evidenced that these not enhance the chromosomal aberrations’ frequency [10]. Similar results were obtained by other authors, in the genotoxicity tests performed in Chinese hamster ovary, as well as in experiments on aquatic organisms (Daphnia magna, Ochrorhynchus mykiss and green algae Pseudokirchneriella subcapitata), acutely exposed to the ultrafine TiO\textsubscript{2} particle-types [11], or in experiments in fish (Nothobranchius rachovi), at which the mitotic index was analyzed in different organs and variants [12], [13].

III. RESULTS AND DISCUSSIONS

A. Characterization of the nanoparticles

The XRD patterns (Fig. 1) analyses present the crystallization as anatase form of the undoped/Au or Fe doped TiO\textsubscript{2}, even if the calcination temperatures for the TiO\textsubscript{2} doping surpass the value of 250ºC. The presence of the dopant in the crystalline network of the titanium dioxide prevents the transition of phases from anatase to rutile. From the diffraction spectra it is noticed that the dopants did not present separate peaks, which means that they are distributed uniformly in the crystalline network. From the surface morphology (SEM) it can be observed that the TiO\textsubscript{2}–Au and TiO\textsubscript{2}–Fe nanospheres’ dimensions range between 10 and 20 nm (Fig. 2, a and b). EDX microprobe provided a semiquantitative elemental analysis of the surface indicating the Ti, O, Au and Fe presence (Fig. 2, c and d).

Figure 1. X-ray pattern of TiO\textsubscript{2} doped: (A) – with Au ions; (B) – with Fe ions.

Figure 2. SEM micrographs of: a. TiO\textsubscript{2}–Au, b. TiO\textsubscript{2}–Fe, EDX spectra of: c. TiO\textsubscript{2}–Au, d. TiO\textsubscript{2}–Fe
From the SEM analyses of TiO$_2$ complexes with α- or β-cyclodextrin (Figs. 3-5), the needle-like, parallelepiped shape of the crystals (or co-crystals) for the undoped TiO$_2$/α-CD and β-CD complexes can be seen. The crystals have much smaller dimensions compared to those of the raw materials (pure α- or β-CD), the length being in the range of 10-100 nanometers, and the width of only a few tens of nanometers. In the case of complexes TiO$_2$-Au/α-CD, the crystals present similar morphologies and dimensions to the undoped TiO$_2$, but these are more agglomerated. In the case of TiO$_2$-Au/β-CD complexes, the crystal morphology is different; the crystals are more uniform, of smaller dimensions, agglomerated, of rhomboidal (generally polyhedral) form. The approximate dimensions of the crystals are between tens and hundreds of nanometers.

### B. Percentage of the normal and aberrant mitotic phases

The percentage of the normal cells, in all experimental variants, recorded inferior values in comparison with untreated Control. In the experimental variants, the percent of normal cells was dependent especially on the nanoparticle types (Table I). Thus, in the treatments with unconjugated TiO$_2$, the percentage of normal cell recorded values of about 96% (except for the variant with β-cyclodextrin in ratio 1:2),

The EDX analyses of the obtained complexes with undoped/doped TiO$_2$ have indicated a higher concentration of Ti in the complexes, especially in the case of α-CD complexation, which can be explained by the fact that pure α-CD and its complexes are more soluble in the water system than β-CD or the corresponding complexes.

The TiO$_2$-Au or TiO$_2$–Fe nanoparticles are disposed on the surface of the α-CD or β-CD (Fig. 6). For the radical treatment, the complex TiO$_2$-Me / cyclodextrin was suspended in distilled water, having as a result an aqueous solution of TiO$_2$-Au or TiO$_2$–Fe nanoparticles in α-CD or β-CD (Figs. 7, 8), without crystalline structure, easily absorbed by the cells.

![Figure 6](image4.png)

**Figure 6.** SEM image with TiO$_2$-Au nanoparticles on the: a. α-CD crystals surface b. β-CD crystals surface.

![Figure 7](image5.png)

**Figure 7.** TEM image with a TiO$_2$-Au suspension in α-CD solution

![Figure 8](image6.png)

**Figure 8.** TEM image with a TiO$_2$-Au suspension in β-CD solution
92-94% in variants with Au-TiO$_2$ and around 95% in the variants with Fe-TiO$_2$.

The normal cell percentage in the presence of TiO$_2$ nanoparticles, without metals or cyclodextrin, recorded values similar to those recorded by the TiO$_2$ nanoparticles complexed with cyclodextrin α or β.

Because the cyclodextrin is a hydrophilic substance and in an aqueous solution these crystals are dissolved, the shape of the cyclodextrin crystals does not influence their absorption in the plant meristem and implicitly the percentage of aberrant or normal cells in different mitotic phases, as well as the structural modifications of the chromosomes and of the mitotic spindle.

### C. Structural modifications of the chromosomes

As a consequence of the free radicals action, the chromosomes are broken, which leads to structural chromosome aberrations. In different phases of the mitosis, or under influence of some substances, the broken ends of the chromosomes can be reunited or not. In the absence of the reunion processes, acentric fragments, minutes, a/o chromosome fragments, are present in anaphase and 11.11% in telophase, while the chromosomal bridges are absent. This feature can be used for the progressive elimination from organism of the cells with a high multiplication ratio (carcinogen cells). At a ratio of 1:1 between the two components, the percentage of acentric fragments is lower (15.73, and 8.86%), the reunion process of the broken ends being also absent.

**TABLE II.** The normal cell percentage in different phases of the mitotic cycle

**TABLE II.** The structural and metabolic modifications of the chromosomes
environmental factors’ effect at the chromosome level, regarding the nanoparticles’ effect at the chromosome level the information is poor. The investigation performed at the Chinese hamster ovary, with TiO$_2$ particles, in the presence or absence of the UV light, evidenced that these not enhance the chromosomal aberrations’ frequency [10]. Similar results were obtained by other authors, in the genotoxicity tests performed in Chinese hamster ovary, as well as in experiments on aquatic organisms (Daphnia magna, Onchorhynchus mykiss and green algae Pseudokirchneriella subcapitata), acutely exposed to the ultrafine TiO$_2$ particle-types [11], or in experiments performed in fish (Notobranchius rachovi), at which the mitotic index (the metaphase number in 100 microscopic fields) was analyzed in different organs and experimental variants [12], [13]. The recorded values were dependent on the organ, being bigger in animals treated with TiO$_2$, in comparison with untreated Control. Other authors [15] analyzed the percentage of chromosomal aberrations induced by three commercial TiO$_2$ types in isolated human lymphocyte cultures. The percentage of chromosomal aberrations depended on the treatment type, the features of the used product, a/o. The anatase crystallization form induced a significant increase of the total chromosomal number, but without establishing a dose – response relation. The main types of recorded chromosomal aberrations were not presented.

D. Metabolic modifications of the chromosomes

The metabolic modifications of the chromosomes affected especially the condensation degree of the chromatin fibre and the synchronisation of this process, and others (Table II). Their presence reveals the action of a stress or an experimental factor which makes the interphase cells enter into mitosis abruptly.

The β-cyclodextrin presence induces a very low percent of reunion of the broken ends, only at a ratio of 1:1.

Complexed with cyclodextrin, the Fe-TiO$_2$ manifested the inhibition of the reunion process of the chromosomes’ broken ends (the absence of the bridges or their presence in a lower percentage), the efficacy being dependent on the cyclodextrin type and the ratio TiO$_2$ : cyclodextrin.

The nanoparticles conjugated with gold or iron, independent of the cyclodextrin type presence and of the ratio TiO$_2$ : cyclodextrin, induced in a small percentage (0.57%-1.92%) the inactivation of the mitotic spindle, as well as the kinetochore inactivation (0.46-1.15%; Fig. 12).

The main metabolic modifications are premature chromosome condensation (PCC; Fig. 13a.), or delay in chromosome condensation (DCC; Figs. 13b, 14), as well as gaps (the uncoloured regions on the chromosome length), differences in condensation degree of the chromatin fibers in eu- and heterochromatin regions of the chromosomes, resulting a banding aspect of the chromosomes (met especially in metaphase), the parallel disposition of the chromatin fibers in prophase, a/o. PCC and DCC were met in a low percentage (0.72-4.08%), especially in variants treated with β-cyclodextrin, independent of the presence or absence of the chelated metal (gold or iron).
The presence of some lyses areas in nucleus in different percentage in almost all treated variants (Fig. 15) underline the presence of an exobiotic factor in the cell.

IV. CONCLUSIONS

The undoped and doped TiO$_2$ nanocrystals used in this experiment presented the anatase form crystallization, the TiO$_2$-Au and TiO$_2$-Fe nanospheres presented dimensions ranging between 10-20 nm.

The TiO$_2$-Me nanoparticles, complexed or not with $\alpha$- or $\beta$-cyclodextrin, presented a different morphology, dependent on the doped metal and cyclodextrin type. The TiO$_2$-Me nanocrystals are present at the surface of cyclodextrin crystals.

In an aqueous solution, cyclodextrin crystals are dissolved and TiO$_2$-Me are suspended in a cyclodextrin solution, being thus absorbed in the meristem cells.

Doped or undoped TiO$_2$ nanocrystals, complexed with $\alpha$- or $\beta$-cyclodextrin, induced both metabolic and structural modifications at the chromosome and mitotic spindle level, depending on the chelated metal, the cyclodextrin type and the ratio TiO$_2$-cyclodextrin (1:2 or 1:1).

As the cyclodextrin is a hydrosoluble substance, the different form of crystals of the complexed TiO$_2$-Me-cyclodextrin, did not influence the percentage of aberrant or normal cells in different mitotic phases, as well as the structural or metabolic modifications of the chromosomes and of the nuclear spindle.

The cyclodextrin type and ratio between TiO$_2$: cyclodextrin influenced both the reunion process of the chromosome broken ends, and the chromosome aberration type.

The $\alpha$-cyclodextrin induced a high acentric fragment percentage in anaphase and telophase, and did not facilitate the reunion processes of the chromosome broken ends (the absence of bridges from cells). For this reason the variant TiO$_2$-$\alpha$-cyclodextrin (ratio 1:2), can be used for the progressive elimination, from organism, of the cells with a high mitotic multiplication rate (carcinogen cells).

The TiO$_2$ conjugated or not with a metal (gold or iron), complexed or not with a cyclodextrin, induced, in a low percentage, the metabolic modification of the chromosomes, their compaction degree in prophase and metaphase being affected (PCC and DCC), as well as the inactivation of the kinetochore or mitotic spindle.
